## Abstract

In contrast with global trends, India has witnessed a secular decline in women's employment rates over the past few decades. We investigate this decline in rural areas, where the majority of Indian women reside. Using parametric and semi-parametric decomposition techniques, we show that changes in individual and household attributes fully account for the fall in women's labor force participation in 1987-1999 and account for more than half of the decline in 1999-2011. Our findings underscore increasing education levels among rural married women and the men in their households as the most prominent attributes contributing to this decline. We provide suggestive evidence that a rise in more educated women's returns to home production, relative to their returns in the labor market, may have adversely affected female labor force participation in rural India.

Key words: female labor force participation, decomposition analysis, education, India

## 1. Introduction

Women's participation in the labor market is often associated with better access to economic opportunities as well as greater decision-making power within the household. Globally, women are joining the labor force in increasing numbers - the gender gap in labor force participation declined by 6 percentage points between 1980 and 2009 (World Bank 2012). In contrast to almost half of the world's female population that is working, only 32.6 percent of India's half a billion adult females report being part of the labor force (United Nations 2013 and India's National Sample Survey (NSS), respectively). This low rate of Indian women's labor market participation is puzzling for a country that has experienced rapid fertility transition (World Bank, various years) and broad increases in women's educational attainment (Census of India 2001 and 2011) along with substantial economic growth over the past two decades.<sup>1</sup> Rather than facilitating entry of women into the labor force, these changes have been accompanied by a consistently low share of women working in urban areas (Klasen and Pieters 2015) and a real reduction in the share of women working in rural areas, between 1987 and 2011 (NSS, own calculations).<sup>2</sup>

Using nationally representative, cross-sectional data from three rounds of India's NSS, we conduct decomposition analyses to examine whether changes in observed demographic and socio-economic characteristics of females can account for the fall in their labor force participation rate (LFPR) in and between the decades of 1987-1999 and 1999-2011. We show that the phenomenon of declining female LFPR over these two decades is concentrated among 25-65 year old, married women in rural India. Focusing in on this demographic group, we decompose changes in their employment rates into two components.

---

<sup>1</sup>India's fertility rate declined from 4.12 in 1987 to 2.60 in 2011. (<http://databank.worldbank.org/data/reports.aspx?source=2&country=IND>). GDP grew at an average rate of 5.94 percent during 1987-1999 and 7.19 percent in 1999-2011. (<http://data.worldbank.org/indicator/NY.GDP.MKTP.KD.ZG?locations=IN>).

<sup>2</sup> 70 percent of India's population continues to reside in rural areas (Census 2011).

The first component is attributable to shifts in demographic and socio-economic characteristics of women over time, for example, improvements in education levels and in household income. Changes in the probability of being employed for women with a given set of demographic and socio-economic attributes drive the second component, for example, variation over time in the probability of working, among women with a given level of education. Throughout the paper, we refer to the first element as the ‘explained’ proportion of the variation in LFPR over time, and the second element as the ‘unexplained’ proportion, since we do not directly observe the factors responsible for this component of change in women’s LFPR.

What factors could explain a decline in female LFPR over time? A view from economic history suggests that the stage of India’s economic development might matter. At very low levels of GDP per capita, women must work in order for families to subsist. With a rise in per capita GDP, as has occurred in India in the past few decades, an income effect tends to lower women’s work force participation. Continued economic growth along with higher incomes and higher wages for women in jobs with lower social stigma induces a substitution effect that outweighs this income effect and increases participation rates of women. Together, these forces tend to lead to a U-shaped curve for female labor force participation (Goldin 1995). Despite this intuitive theory, empirical evidence for the U-shaped relationship is mixed (Lahoti and Swaminathan (2013) for India). Using panel data methods, Tam (2011) finds evidence in support of the hypothesis using data from 1950-1980 for 130 countries. In contrast, Gaddis and Klasen (2014) are not able to establish the ‘U’ shaped relationship between economic growth and women’s work force participation using data for additional years. Moreover, the evidence on the relationship between higher educational attainment of women and their LFPR is ambiguous. While the greater supply of female high school graduates, coupled with an increased demand for clerical jobs, led to a

more than 15 percentage point increase in the labor force participation rates of women in the U.S. between 1930 and 1950 (Goldin 1995), the picture is heterogeneous in developing countries (Das and Desai 2003; Aromolaran 2004; Lincove 2008). Analyzing five Asian countries (Indonesia, Korea, Philippines, Sri Lanka and Thailand), Cameron, Dowling and Worswick (2001) find that female labor force participation rates respond differently to education across countries due to two potentially opposing effects: a wage effect and a bargaining power effect. Higher wages encourage women to join the workforce because the opportunity cost of time at home rises. However, if more education increases the relative bargaining power of women, and women prefer leisure or home production to working in the market, increasing levels of female education could lead to a fall in women's labor force participation. Moreover, even if female returns to education in the labor market rise, they may not rise fast enough to counteract the rise in the returns to education in the marriage market (Behrman et al. 1999) and in home production. For example, Lam and Duryea (1999) show that as Brazilian women get more schooling, total fertility falls and wages rise, but the share of women working does not increase. They hypothesize that in Brazil, home productivity effects are large enough to offset increases in market wages up to the first 8 years of education.

Several studies have offered specific explanations for the decline in female LFPR in rural India: increases in female enrollment in higher education, increases in real household incomes reducing the need for females to engage in wage work, and limited growth in employment opportunities for females (e.g. Sorsa et al. 2015; Neff, Sen and Kling 2012; Kannan and Raveendran 2012; Chowdhury 2011; Himanshu 2011).<sup>3</sup> However, these studies do not quantify the relative importance of multiple factors that can explain the decline.

---

<sup>3</sup> Das et al. (2015) analyze the relationship between labor market rigidities and female labor force participation, distinguishing between formal and informal sector employment, using NSS data for 1993-94 to 2011-12.

Kapsos, Silberman and Bourmpoula (2014) undertake a decomposition exercise using the NSS and state the explained component using coefficients from a pooled regression of female employment on characteristics for all the years under consideration. They do not analyze the contribution of each characteristic to the explained component. Chatterjee, Murgai and Rama (2014) focus on the demand side, controlling for district level employment in agriculture, non-farm employment, and casual work as a proportion of total population. However, these may also reflect supply side factors since all that we observe in the data is equilibrium employment.

In a recent paper, Klasen and Pieters (2015) address the puzzle of working women in India by focusing on the stagnant labor force participation among urban Indian women, which they attribute to both demand and supply side factors. Using parametric decomposition analysis (Blinder-Oaxaca) similar to ours, they find that on the supply side, rising household incomes and household heads' education reduced female LFPR in urban India while increases in female education raised participation. They conclude that these two opposing effects have contributed to the stagnation of female LFPR in urban India.

Our paper adds to the literature on women's labor force participation broadly and in India, particularly, in several ways. First, this paper extends the existing literature by quantifying how much of the fall in female LFPR in rural India is accounted for by changes in the demographic and socio-economic characteristics of working age females between 1987 and 2011. We estimate the contribution of each characteristic to the fall, using parametric and semi-parametric decomposition methods. Second, unlike the recent debates in India that focus only on the decade of 1999-2011, we underline the fact that the decline in women's LFPR is not a recent phenomenon but a long-term trend in rural India. In contrast to Klasen and Pieters (2015) who examine LFPR trends between 1987 and 2011, we break up the period under study into 1987-1999 and 1999-2011 to compare our results between the decade

of slower decline to that of faster decline in women's LFPR. This allows us to see whether factors that contribute to the decline in female LFPR differ between the two decades due to the 1991 economic reforms (Topalova 2010). Third, we highlight the role of and a potential mechanism through which women's education affects their decision to participate in the labor market. While Klasen and Pieters (2015) find evidence of women's own education contributing to a moderate *increase* in urban women's LFPR our analysis underlines the significant role of women's education in the *reduction* of their LFPR in rural areas as their schooling rises from low levels. Different initial levels of education among urban and rural women are potential reasons for why increases in education play a disparate role in affecting LFP across the two studies.

Our findings nuance the existing evidence by suggesting that the reasons behind the decline in rural women's work force participation vary across decades. Changes in observable demographic and socio-economic characteristics of married women completely explain the fall in their LFPR for the period 1987-1999, and explain up to 56 percent of the change in their LFPR between 1999 and 2011. The explanatory power of women's individual and household characteristics in the secular decline of their LFPR is large, although their importance appears to be falling over time. We do not find strong evidence that observable variables correlated with social stigma against women working outside the home (e.g. caste, religion) can account for a substantial proportion of the fall in women's LFPR over time.

More importantly, we find that increases in both women's and men's education plays a substantial role in explaining the decline in both decades. Between 1987 and 1999, we estimate that women's own education and that of the men in their household accounted for 87-95 percent of the overall decline in women's LFPR. In the 1999-2011 decade, they explain 23-35 percent of the total decline in women's LFPR. Although the role of men's education could reflect, at least in part, the effect of rising incomes, the rise in household

income (proxied by consumption expenditure) accounts for no more than 16 percent of the decline in 1987-1999 while its effect is inconsistent in 1999-2011. This finding differs from the urban setting, where increases in income (estimated through imputed male earnings) reduces LFPR of women over the same period (Klasen and Peters 2015). All of our results are robust to both parametric and semi-parametric decomposition methods.

The stylized facts we document - that the fall in employment has occurred only among married women in rural India, at the same time that their participation in domestic work and their average level of education is increasing - suggests a possible reason for their declining LFPR: education increases female productivity in the home. If primary education provides basic skills to mothers in India, this may have a larger impact on their home productivity relative to their market productivity (e.g. Lam and Duryea 1999). Women may choose to invest in their homes, including their children's education and health, as they get more educated and their reservation wage rises. Consequently, women's labor supply may fall with more education even though education also raises the opportunity cost of not working. Although we cannot test this labor supply channel directly, we show that the same observable factors that account for the decline in female LFPR over the two decades also account for the increase in female participation in domestic work.

In the next section we discuss the data we use in our analysis. In Section 3 we describe the decomposition methodology which quantifies the contribution of changing socio-economic characteristics to women's LFPR decline in India. We discuss results in Section 4 and conclude in Section 5.

## **2. Data**

We use the Employment and Unemployment rounds of India's National Sample Surveys (NSS) in 1987-88, 1999-00 and 2011-12 (referred to as 1987, 1999 and 2011 in this paper).

The surveys include repeated cross-sections of households, selected through stratified random sampling, that are representative of the country's population.<sup>4</sup> The NSS provides data on individual and household characteristics – household composition, religion, social group, landholding, monthly consumption expenditure as well as age, education, marital status, and participation and earnings in the labor market. Throughout our analysis we measure an individual's labor force participation using the 'Usual Principal and Subsidiary Status (UPSS)' in the NSS which classifies a respondent as working or not working (inactive) during the reference period of 365 days preceding the date of survey (see Appendix A for details).<sup>5</sup> We define a person as participating in the labor force if they are working or seeking work.

Figure 1 shows the LFPR of 15-65 year old men and women in rural and urban India. LFPRs are significantly higher for men and higher in rural areas. While labor force participation has been declining for 15-65 year old females and males in both rural and urban areas, the decline is most dramatic for rural women: 14 percentage points between 1987 and 2011.<sup>6</sup> When we restrict our sample to ages 25-65 in Figure 2, there is almost no fall in the male LFPR over time. The differences between these two figures suggests that increasing school enrollment among men in the 15-24 year old group accounts for the reduction in male LFPR during 1987-2011 (National Sample Survey Office 2015). In contrast, women in the

---

<sup>4</sup> The NSS follows a two stage sampling design: In rural areas, the first stratum is a district. Villages are the primary sampling units (PSU), picked randomly in a district with equal number of households surveyed in each quarter (over an entire agricultural year of July to June) to ensure equal spacing of observations across the year. The households are randomly chosen in the selected PSUs.

<sup>5</sup> We define the labor force participation rate (LFPR) as the proportion of people currently working or seeking work. Besides UPSS, the NSS provides another measure of labor force participation status - 'Daily Status' - the number of days worked in the preceding *week* before the survey date. We do not use this measure in our analysis because the daily status employment rates in 1987 are not comparable to 1999 and 2011 due to a change in survey methodology. While these changes are unlikely to affect the employment rate using UPSS they can artificially increase the employment figures by daily status. However, none of our conclusions change if we use 'daily status' as our measure of employment.

<sup>6</sup> The decline in LFPR is 6 and 3 percentage points for rural and urban males, respectively, during this period. Urban women's LFPR declined by 3 percentage points between 1987 and 2011. The proportion of rural women looking for work has not changed during this period (NSS, various years). This suggests that it is not unemployment which is the cause of decline in women's LFPR.

older age group of 25-65 still exhibit a declining trend over time, and substantially so in rural areas. The fall in women's LFPR has been steeper between 1999 and 2011 (9 percentage points) than in the previous decade (3 percentage points). In Figure 3, we show that currently married women are the ones driving this decline in work force participation. Married women are 85 percent of rural women in the 25-65 age group.<sup>7</sup> In Figure 4, we see that the decline in rural married women's LFPR has been accompanied by an almost equivalent increase in the proportion of women who report domestic work as their primary activity in the previous 6 months during 1987-2011 (from 55 percent in 1987 to 69 percent in 2011).<sup>8</sup>

For the decomposition analyses we restrict our sample to 25-65 year old married women in rural India and use weights to make our results nationally representative. Table 1 shows summary statistics of the explanatory variables used in the decomposition analysis for each of the three rounds of the NSS. The individual variables include the female age distribution (seven indicator variables for age groups with age group 25-29 as the omitted category) and education distribution (six indicator variables with illiterate as the omitted category). Household-level variables include land owned by a household (five categories with the landholding size of less than 0.1 hectare as the omitted category) and household consumption expenditure (per capita) deciles (ten indicator variables with the first decile omitted). Since the NSS does not contain information on the income of households, we proxy for income using monthly household consumption expenditure (e.g as in Mammen and Paxson 2000). We create deciles of household monthly per capita consumption expenditure using the data for 1987. To apply these deciles to later years, we adjust the 1987 cut-offs

---

<sup>7</sup> For never married females there has, in fact, been an increase in LFPR between 1987 and 2011. The share of married women in 1987, 1999 and 2011 was 82.5, 85.4, 87.5 percent, respectively (NSS survey rounds). The small but significant increase in this proportion is attributable to a lower proportion of widowed women due to falling mortality rates in India.

<sup>8</sup> Domestic work in the NSS includes domestic chores and not-for-wages collection of goods (vegetables, roots, firewood, cattle feed, etc.), sewing, tailoring, weaving, etc. for household use. The difference between women's LFPR and the share of women in domestic work is the share of women unemployed in the previous year.

using the consumer price index for agricultural laborers, and convert these cut-offs to nominal values in 1999 and 2011.<sup>9</sup> This ensures that consumption expenditure deciles are comparable across years while also taking into account the absolute expenditure levels within each year. The final set of household-level variables includes the highest level of education of male members in a household (six indicator variables with illiterate as the omitted category).<sup>10</sup> Since the NSS does not provide relationship codes, we cannot match women to their husbands within households. Instead, we define male education as the highest education level among all 18-65 year old, married male members of the household. This variable is a proxy for male earnings in the absence of self-employment income in the NSS. It also captures positive assortative matching on education, a feature of the Indian marriage market that has become more prevalent during the period of our study.<sup>11</sup>

Table 1 shows that while there have been no significant changes in the age distribution of women, women's illiteracy rates have fallen dramatically from 80 to 54 percent between 1987 and 2011. The land ownership structure between 1987 and 2011 shows an increase in households with smaller landholdings. Real household consumption expenditures have increased with a larger percentage of women in the upper deciles of real household income in 2011 relative to 1987. The educational attainment of men in the

---

<sup>9</sup> To illustrate, the first decile in 1987 contains households having a monthly per capita expenditure of less than Rs. 76. In nominal terms Rs. 76 in 1987 is equivalent to Rs 213 and Rs 429 in 1999 and 2011 respectively. Rs. 213 is then defined to be the cut-off for the first decile in 1999. Similarly, Rs 429 is defined to be the cut-off for the first decile in 2011. Our results are unchanged when we include household consumption expenditure as a continuous, non-linear variable.

<sup>10</sup> The NSS provides data on the highest level of completed education and not years of schooling of household members. Therefore, to avoid measurement error in calculating the average years of schooling of men in the household we use the maximum level of male education. However, our results do not change if we use average education years. Other household characteristics which could possibly explain changes in women's employment, such as household size, share of children under age five, share of male members, caste and religion have not been included in the main regressions since they do not alter our main conclusions. Also, some of these characteristics (e.g. fertility) can be endogenous to the labor force participation decision. The decomposition results including these variables are shown in robustness checks in Appendix B.

<sup>11</sup> The correlation between education of 18-35 year old daughters-in-law in the household with the highest education of married males who are sons of the household head has increased from 0.54 in 1987 to 0.63 in 2011. We reach the same conclusion of a rise in positive assortative mating on education if we use the average level of education of males in the household.

household has also increased, with a significant reduction in illiterate men (26 percent from 45 percent) and a larger proportion of married men completing at least middle school and above during this period. Notice that there has been virtually no change in the caste and religious composition of the women in this age group during 1987-2011.

### 3. Methodology

We use parametric and semi-parametric decomposition methods to estimate the proportion of the decline in women's LFPR that is accounted for by the changing demographic and socio-economic characteristics of women and the households they live in. We divide the data into two periods – 1987-1999 and 1999-2011 – to account for structural changes post liberalization of the economy in 1991 (e.g. Topalova 2010). In the next section, we describe each decomposition technique. We refer to employment rates interchangeably with LFPRs, because there is no change in the unemployment rate of rural women over time.

#### 3.1 Parametric Decomposition: Blinder-Oaxaca

We first use the non-linear Blinder (1973) and Oaxaca (1973) technique to decompose the change in employment rates of women over time. We estimate the following reduced form logit model for each of the three years in our cross-sectional datasets:

$$\hat{Y}_i^j = F(\mathbf{X}_i^j \hat{\beta}^j) \quad (1)$$

where  $Y$  is the binary outcome variable - woman  $i$ 's participation status in the labor force (=1 if the woman is currently in the labor force and 0 otherwise) in year  $j$ .  $\mathbf{X}$  includes all individual and household characteristics as discussed in Table 1, and  $\hat{\beta}^j$  are the parameter estimates. We examine the pattern of  $\hat{\beta}^j$ s estimated using the participation logits for each decade to gain some insight into the “returns” that changed, contributing to the decline in female LFPR.

We use the estimated  $\hat{\beta}^j$  to decompose the predicted differentials in participation rate between 1987 and 1999 using the coefficient estimates from (1) as follows:

$$\begin{aligned} \bar{Y}^{1987} - \bar{Y}^{1999} = & \left[ \sum_{i=1}^{N^{1987}} \frac{F(\mathbf{X}_i^{1987} \hat{\beta}^{1987})}{N^{1987}} - \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{1987})}{N^{1999}} \right] \\ & + \left[ \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{1987})}{N^{1999}} - \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{1999})}{N^{1999}} \right] \end{aligned} \quad (2)$$

Here  $\bar{Y}$  is the mean employment rate, and  $N$  is the population size. The superscripts reflect the year of measurement.

The first term in square brackets, on the right hand side of equation (2), represents the change in women's LFPR that can be attributed to their changing demographic and socio-economic characteristics ( $\mathbf{X}_i$ ) over time holding the coefficients ( $\hat{\beta}^{1987}$ ) constant. We refer to this as the explained component of the variation in LFPR over time. The second term represents the change in women's LFPR holding  $\mathbf{X}_i$  constant while varying the coefficients over time. It shows the change in women's LFPR explained by women with the same characteristics having different participation rates over time. We call this the unexplained component of the variation in LFPR over time. Dividing the explained (unexplained) component by the total change in female employment (i.e. the left hand side of (2)) gives us the explained (unexplained) proportion of the change in women's LFPR over time. Equation (2) shows one version of the decomposition, when the coefficients for 1987 ( $\hat{\beta}^{1987}$ ) define the reference relationship between female employment and individual characteristics. However, shifts in the structure of the economy, such as a change in the supply or demand for women's labor could change the relationship between women's employment and their characteristics over time. For instance, if  $\hat{\beta}^{1999} < \hat{\beta}^{1987}$  for women in low-income households, this could be because either female labor supply in these households or labor

demand for these women fell (or a combination of the two). We will not be able to distinguish between these two explanations. Instead, we estimate the explained proportion at the regression coefficients for two benchmark years 1987 ( $\hat{\beta}^{1987}$ ) and 1999 ( $\hat{\beta}^{1999}$ ) and discuss whether our findings differ depending on the specific year used to construct the decomposition.

In addition, any interaction effects between changing attributes and changing coefficients might contribute to the variation in female LFPR over time (e.g. Biewen 2012). For example, if households own less land over time, and if probability of working in the market falls with time for women belonging to a land owning household, then the combination of these two changes would account for a lower proportion of any decline in female LFPR. We outline the role of these interaction terms more formally in Appendix B, and show how the total decomposition that we implement in (2) incorporates any potential interaction effects.

### 3.2 Semi-Parametric Decomposition

In a second approach, we use a generalization of the Blinder-Oaxaca approach— a semi-parametric decomposition method first proposed by DiNardo, Fortin and Lemieux (1996) (henceforth, DFL), which does not impose a linear relationship between the dependent variable and the explanatory variables.<sup>12</sup> We outline the DFL decomposition method below using the same notations as in Black, Tseng and Wilkins (2011).

---

<sup>12</sup> DiNardo (2002) shows that the DFL method is identical to Blinder-Oaxaca decomposition when the variable of interest is the mean of the outcome variable and there is a single categorical explanatory variable. While this technique has been used to decompose wage and earnings differentials (Leibbrandt, Levinsohn, and McCrary 2010; Biewen 2001; Butcher and DiNardo 2002; Hyslop and Mare 2005; Daly and Valletta 2006), only a handful of papers have used it to decompose differences in other outcomes, such as, employment (Black, Tseng and Wilkins 2011) and health (Geruso 2012).

Let  $E(e| x, t)$  denote the expected (mean) employment rate for people with a set of characteristics  $x$  at time  $t$  and let  $f(x|t)$  denote the distribution of characteristics at time  $t$ .

The aggregate employment rate at time  $t$  can then be expressed as

$$E(e|t) = \int E(e| x, t) f(x|t) dx \quad (3)$$

The notation highlights the fact that both the employment-characteristic relationship ( $E(e| x, t)$ ) and the distribution of characteristics ( $f(x|t)$ ) can vary over time. To quantify the share of the fall in women's employment accounted for by the change in demographic and socio-economic characteristics of women (i.e. by changes in  $f(x|t)$ ) we construct counterfactual employment rates as follows. We denote the time for which the set of employment rates for each characteristic is drawn by  $t_e$ , and the time from which the distribution of characteristics is drawn by  $t_x$ . The average employment rate at time  $t$  can then be alternatively expressed as,

$$E(e| t_e = t, t_x = t) = \int E(e| x, t_e = t) f(x|t_x = t) dx \quad (4)$$

where  $E(e| t_e = 1987, t_x = 1987)$  denotes the observed employment rate in year 1987 given 1987 characteristics, while  $E(e| t_e = 1987, t_x = 1999)$  denotes the counterfactual employment rate in 1987, i.e. the employment rate that would have been observed in 1987 had the distribution of individual characteristics been given by the distribution in 1999.

Holding the base year (1987) employment-characteristic relationship constant over time (analogous to the  $\hat{\beta}^j$  in the parametric approach), we can decompose the change in aggregate employment between 1987 and 1999 into two components. The first is an explained component, or a change in employment due to change in socio-economic characteristics of working age women. The second is an unexplained component, or a change in employment due to change in employment rates of women with same characteristics. We can write this as:

$$\text{Total change} = \text{Explained change} + \text{Unexplained change}$$

$$\begin{aligned}
& E(e|t_e = 1987, t_x = 1987) - E(e|t_e = 1999, t_x = 1999) \\
&= [E(e|t_e = 1987, t_x = 1987) - E(e|t_e = 1987, t_x = 1999)] \\
&+ [E(e|t_e = 1987, t_x = 1999) - E(e|t_e = 1999, t_x = 1999)] \tag{5}
\end{aligned}$$

where the counterfactual employment rate in 1987 is given by:

$$\begin{aligned}
E(e|t_e = 1987, t_x = 1999) &= \int E(e|x, t_e = 1987) f(x|t_x = 1999) dx \\
&= \int E(e|x, t_e = 1987) \varphi(x) f(x|t_x = 1987) dx \tag{6}
\end{aligned}$$

$\varphi(x)$  is a re-weighting function which we use to adjust the distribution of characteristics in one year to look like the distribution of characteristics in a different year. We apply Baye's rule to get this re-weighting function:

$$\varphi(x) = \frac{\Pr(t_x = 1987) \Pr(t_x = 1999|x)}{\Pr(t_x = 1999) \Pr(t_x = 1987|x)} \tag{7}$$

Where  $\Pr(t_x = t)$  is the percentage of observations that belong to year  $t$ . The estimate for  $\Pr(t_x = t|x)$  is obtained by estimating a discrete choice model where the dependent variable is a dichotomous variable for the observations belonging to year  $t$  and  $x$  are the explanatory characteristics. Then,  $\varphi(x)$  is constructed using the predictions for each individual in year 1987.

The counterfactual employment rate that is part of (6) can then be empirically constructed as

$$\hat{E}(e|t_e = 1987, t_x = 1999) = \sum_{i=1}^{N_{1987}} \frac{\hat{\varphi}_i(x) e_i}{N_{1987}} \tag{8}$$

where  $(\hat{\varphi}_i(x))$  is the estimated re-weighting function and  $e_i$  is whether or not a woman is in labor force in year 1987. The estimated re-weights  $(\hat{\varphi}_i(x))$  are such that the distribution of observed characteristics across years is the same.<sup>13</sup>

---

<sup>13</sup> For example, in the above case, the observations in year 1987 are re-weighted such that the distribution of observed characteristics in 1987 is identical to that in 1999. If real income is higher in 1999, then a larger re-

We use both the Blinder-Oaxaca decomposition and the DFL decomposition to estimate the explained component of variation in LFPR over time using counterfactuals in 1987 and in 1999. We then repeat these exercises for the 1999-2011 decade and compare our results across methodologies and over time.

## **4. Results**

### **4.1 Estimates from LFPR logits for each decade**

Before turning to the results of our decomposition analysis, we briefly discuss the reduced form relationships between female education and female LFPR (Figure 5), as well as the logit regressions of a woman's labor force participation status on her socio-economic characteristics for 1987, 1999 and 2011 (Table 2). A few findings stand out.

First, the role of women's education in determining their LFPR is salient across all education categories between 1987 and 2011. Figure 5 shows a 'U'-shaped relationship between rural women's education and LFPR. This pattern is also reflected in the results of Table 2. Education raises women's LFPR, but only at the highest level of schooling ('more than graduate') after 1999, in comparison to 1987 when the coefficient turns positive at 'higher secondary' level. This provides a clue as to why patterns of LFPR among rural and urban women may differ. Table 1 showed us that the majority of women in rural areas are on the declining portion of this 'U'-curve, given their low level of average schooling.<sup>14</sup> In contrast, women in urban areas have higher average levels of education and appear to be on the upward portion of the 'U'-curve (Klasen and Pieters 2015). Second, Table 2 shows that

---

weight is given to the individuals belonging to households having a higher income in 1987 so that the percentage of individuals in each income decile after re-weighting is identical across years.

<sup>14</sup> In urban India, the proportion of 25-65 years old married women with higher secondary and graduate education has risen dramatically - from 13 to 25 percent and 6 to 18 percent, respectively - between 1987 and 2011. In contrast, Table 2 shows the percent of rural women with higher secondary schooling or above rose from only 2 to 11 percent over the same period.

the effect of income (using consumption expenditure deciles as a proxy) on women's labor market participation has become weaker over time and is mostly insignificant in 2011. Third, male education continues to have a robust and negative impact on women's LFPR, albeit less significantly at lower levels of education. It is possible that some of the negative effects of rising household income on women's LFPR are also captured by increasing male education. However, due to positive assortative matching in Indian marriage markets it is likely that the effects of rising male education also include those of increasing female education. These broad patterns in each decade are robust to including caste, religion, and other demographic variables, as well as district fixed effects (results available upon request).<sup>15</sup>

#### **4.2 Proportion of decline in women's LFPR explained by socio-economic characteristics**

Our main results from the decomposition analyses appear in Tables 3 and 4. We first estimate changes in female LFPR between 1987 and 1999 (i.e. 1987 less 1999) and then between 1999 and 2011 (similarly, 1999 less 2011). The changes are therefore positive, capturing the declining female LFPRs over time.

Table 3 shows the parametric decomposition results. The specifications across columns differ in the individual and household characteristics included in the analysis. We include age of the woman and her education as the only explanatory characteristics in the first specification (column (1)). Columns (2) and (3) add household land ownership and household consumption expenditure controls, respectively. In column (4), we replace household consumption expenditure with the highest level of education among men in the household,

---

<sup>15</sup> We also include the proportion of household members who are in the 0-5 and 6-14 age group and interact them with woman's education to assess if there are any trends in the relationship between child care, women's education and their LFP. We find a negative relationship between children aged 0-5 years and women's LFPR in all years, particularly for women in the 25-45 age group. The interaction between women's education levels and children in this age group is negatively associated with women's LFP, with a striking shift in significance from low to higher education levels between 1987 and 2011. We do not find any significant relationship between women's education and the proportion of children in the 6-14 age group. These results are available on request.

which is more likely to be exogenous to women's LFPR than household expenditure. Column (5) includes all of these demographic and socio-economic characteristics.<sup>16</sup>

Panel A of Table 3 shows the decomposition results for the change in women's LFPR between 1987 and 1999. We calculate the explained proportion of the total predicted change in female LFPR by dividing the explained component by the total change in predicted LFPR. For instance, in Panel A column (1), the explained proportion at 1987 coefficients is  $0.0210/0.0310 = 0.68$ . This means that the changing structure of female education and the distribution of women across age groups can account for 68 percent of the change in female LFPR between 1987 and 1999, keeping the 1987 coefficients constant. Across specifications in Table 3, Panel A, the share of the change in female LFPR that can be explained by observables varies from 68 to 136 (70 to 141) percent when we use the 1987 (1999) coefficients. The explained proportions using 1987 coefficients are similar to the explained proportions using 1999 coefficients. When all variables are included, the share of the change that we can account for is 136 (141) percent evaluated at the regression coefficients for the year 1987 (1999). This implies that the included demographic and socio-economic attributes fully explain the fall in women's LFPR between 1987 and 1999. Explained proportions greater than one suggest that if only these attributes were responsible for the change in women's LFPR during this period, then the fall in female LFPR should have been larger than we observe. In other words, the effects of the included variables on the change in female LFPR must have changed size, and possibly their direction of influence, over time.

Panel B shows the decomposition results for 1999-2011. When all the demographic and socio-economic characteristics of women are included in our analysis (column (5)), only

---

<sup>16</sup> Socio-economic factors which show minor or no change in distribution (for example, social group, religion, number of male members in household) or that exhibit a change in a direction that cannot explain the fall in women's LFPR (e.g. number of children, household size) have not been included in our specifications in Tables 3 and 4. We show that our main results are robust to including these additional variables in Appendix B, Table B.2.

56 (16) percent of the decline in women's LFPR in this period can be explained at the 1999 (2011) employment regression coefficients as indicated in column (5). Thus, we can account for a higher proportion of the fall in women's LFPR during 1999-2011 using the 1999 coefficients than using the 2011 coefficients. As discussed earlier, the employment regression coefficients for 1999 are likely to reflect the relationship between employment and individual characteristics given specific labor demand conditions in 1999. Changing labor demand over time, especially in response to the economic reforms of the 1990s, could have altered the observed relationship between characteristics and employment by 2011. We discuss this issue in more detail later.

We can use our methodology to understand whether there are interaction effects between changing characteristics and changing coefficients that predict the variation in female LFPR. For example, Table 1 shows that the proportion of women with schooling has risen across all education categories in rural India. At the same time, the logit estimates in Table 2 show that as education increases from low levels, women are less likely to work, and over time, the coefficients on all categories of education have increased in absolute magnitude (when compared to illiterate women) in 2011 as compared to 1999. The effect of this increase in women's education combined with the change in the corresponding coefficients will therefore be to reduce female LFPR by even more than the effects of the changes in coefficients, or changes in characteristics, alone.

Algebraically, these interaction effects are equal to the difference in the explained proportions evaluated at each of the two sets of coefficients (e.g. see Biewen 2012). For example, in column (5) of Table 3, this interaction effect is equal to  $56 - 16 \approx 39$  percent. The results in Table 3 show that there are larger gaps between the explained proportions of the change in female LFPR using the 1999 or 2011 coefficients (Panel B), compared with smaller gaps between the explained proportions using the 1987 or 1999 coefficients (Panel A). This

suggests that the role of interactions between the changes in the socio-economic characteristics of interest and the coefficients has become more important over time. We provide a longer discussion and illustration of computing these interaction effects in Appendix B, and Table B.1.

Moving on to Table 4, we show results from the semi-parametric DFL decomposition technique. For brevity, we show only the calculated explained proportions (that is, the share of the predicted variation in female LFPR accounted for by the specific set of observable characteristics). Panel A indicates that between 67 and 141 percent (69 and 146 percent) of the fall in women's LFPR between 1987 and 1999 can be explained, depending on the demographic and socio-economic characteristics we include, at the counterfactuals for 1987 (1999). Similarly, 34-60 percent (13-19 percent) of the fall in women's LFPR between 1999 and 2011 is accounted for by the included characteristics at the counterfactuals for 1999 (2011) in Panel B. These explained proportions are comparable to those obtained in Table 3 using Blinder-Oaxaca decomposition. The largest difference in the explained component obtained by the two methods is for the 1999-2011 period. In this case, the Blinder Oaxaca decomposition tells us we can account for 56 (16) percent of the predicted change between 1999 and 2011, while the DFL estimate accounts for 60 (13) percent of the predicted change at 1999 (2011) coefficients (comparing column (5) in Tables 3 and 4).

To check the validity of the semi-parametric results, Black, Tseng and Wilkins (2011) suggest conducting  $t$  tests for individual variable means, across the re-weighted observations in the base year and the actual observations in the other year(s). The null of equality of means is more likely to be accepted when the re-weighting function is precisely estimated for which, they advocate inclusion of interaction terms among the characteristics. As a robustness check, therefore, we show the DFL decomposition results when all two-way interaction terms between observables are included as explanatory variables while estimating the re-weighting

function in column (6) of Table 4.<sup>17</sup> These estimates are comparable to those shown in column (5), in which we do not include interaction terms among the set of characteristics, suggesting that there are no important non-linearities that we have omitted in our analysis.<sup>18</sup>

### 4.3 Contribution of characteristics to the predicted changes in female LFPR

While the similarities in the explained proportions estimated using both the parametric and the semi-parametric techniques give us confidence in the Blinder-Oaxaca decomposition, it only provides a general picture of how the set of included observables, along with the year-specific coefficients on these variables, account for the changes in female LFPR over time. To better understand the *relative* role of different characteristics, we use a method proposed by Fairlie (2005). For each specific observable characteristic, we estimate how much of the total predicted change in female LFPR is accounted for by that characteristic and its year-specific coefficient, conditional on the other variables included in the regression. We do this using the Blinder-Oaxaca analysis, in Table 5.

Panel A shows the contribution of each characteristic to the total explained component (in bold) in 1987-1999 at the regression coefficients for 1987. We obtain this by dividing the characteristics' contribution (in the row below the bold figures) by the total explained component for that specification in Table 3. For instance, in specification (1), woman's education contributes fully to the explained proportion, because  $0.0213/0.0210 \approx 1.02$ .<sup>19</sup> In specifications (2) and (3) we include land and household consumption expenditure, and we see the contribution of education to the explained proportion of change in female

---

<sup>17</sup> For instance, we interact age group indicators with education, land owned, income, male education and own education separately.

<sup>18</sup> In specification (6), the re-weighting function is unable to match the age-group composition at statistically significant levels, for the decomposition in 1987-1999, but the absolute differences are not large. For example, in Panel A, specification 6, the re-weighted observations in 1987 have an age group composition of 22, 20, 17, 13, 11, 8 and 10 percent for age groups 25-29, 30-34, 35-39, 40-44, 45-49, 50-54 and 55-65, respectively. The corresponding numbers for actual population in 1999 provided in Table 1 are very close to these proportions.

<sup>19</sup> Rounding off errors in Table 5.

LFPR falls to 81 and then 58 percent due to the correlations between all the included variables. However, as we look across columns (1) – (3), woman’s own education continues to be the largest contributor to the explained proportion of changing female LFPR. Adding controls for the education of men in the household, in columns (4) and (5) reduces the contribution of women’s education to the explained component by more than half. This likely indicates strong positive assortative matching: women matching to men at the same levels of education in the Indian marriage market (Dalmia 2011), but may also reflect the effect of rising household incomes. The rise in men’s education constitutes 54 to 62 percent of the explained component of the fall in women’s LFPR between 1987 and 1999. Across all columns for Panel A, women’s own education and the education of the men in their household together can account for 70 to 84 percent of the explained component of the decline in women’s LFPR between 1987 and 1999.

Decrease in per capita landholding of the household contributes 17 to 22 percent to the explained component during this period across specifications in Panel A. This is likely because women belonging to households with more land have a larger probability of being employed, primarily due to self-employment on own land. Increases in household consumption expenditure constitute 12 to 21 percent of the explained component of the fall in women’s LFPR during 1987-1999, depending on the specification we use. The results follow a similar pattern when the explained proportion is evaluated at the 1999 coefficients – with own and male education contributing between 62 and 75 percent to the explained component.

During the 1999-2011 decade (Panel B of Table 5) increases in women’s and men’s education were again the largest contributors to the explained proportion. When all the characteristics are included (column 5), women’s education constitutes 28 (47) percent of the explained component at 1999 (2011) coefficients. Similarly, male education contributes 35 (95) percent to the explained proportion. Change in households’ landholdings contributes

little to the explained component during this decade as shown in Panel B. Of note is the role of household consumption expenditure in predicting the fall in female LFPR. While household consumption expenditure accounts for 36-45 percent of the explained component when evaluated at the regression coefficients for 1999, the negative proportion obtained for the 2011 coefficients suggests that increases in consumption expenditure should have resulted in an *increase* in women's LFPR during this period. In other words, because the overall change in female LFPR is negative, rising household expenditures should have mediated this decline (the opposite of what we usually think of as an income effect). The effect of increasing household consumption expenditure is not consistent over time (Table 2). Overall, the magnitude of the contribution of the non-education variables to explaining female LFPR between 1999 and 2011 is significantly smaller than the contribution of the education variables.<sup>20</sup>

Based on the figures in Table 5, we can estimate the contribution of education to the actual decline in women's LFPR. In specification (5) of Table 5, Panel A, the contribution of women's education to the explained variation in LFPR over the first decade is 16 percentage points while the explained proportion is 136 percent (Table 3) at the regression coefficients for 1987. This implies that changes in women's education over time explain about 21.8 percent ( $=0.16 \times 1.36$ ) of the total decline in female LFPR. Using this method, we estimate that women's own education and that of the men in their household (specification 5) accounts for between 87-95 percent of the overall decline in women's LFPR in 1987-1999 depending on whether we use 1987 or 1999 coefficients. In the 1999-2011 decade they explain 23-35

---

<sup>20</sup> The proportion of explained variation falls when additional variables are included in Appendix B, Table B.2. The female characteristics continue to explain the entire fall in female LFPR between 1987 and 1999 but the explained proportion between 1999 and 2011 falls to 48 percent. This is because household size and number of children under age five has fallen over time. This change should increase the female LFPR. Social group membership and male members do not contribute much to the explained proportion. The only additional characteristic which contributes to the decline in female LFPR between 1999 and 2011 is the change in religious composition. This is because the proportion of population that is Muslim has increased, and Muslim women tend to have lower participation rates in the labor market. Our main conclusion remains: individual and household characteristics (in particular education) play the most important role in explaining declining LFPR.

percent of the total decline in women's LFPR. In both decades, education is the largest contributor to the decline in women's LFPR. This is in contrast to what we might have expected - that increasing female education is associated with an increase in women's work.

Before turning to a broader discussion of results, it is worth noting the relatively large role of men's education in each of the decomposition analyses. Increases in male education often represents the importance of rising household income, although we are controlling for household income through its proxy, consumption expenditure and land ownership.<sup>21</sup> However, because of the increasing degree of positive assortative matching in India over the past decades, the role of rising men's education in accounting for the decline in female LFPR cannot easily be separated from women's changing preferences about time allocation. While raising men's education is unlikely to directly increase female productivity in the home, the correlation of education levels within a marriage means that men's education in our decomposition analyses may be capturing some of the effects of rising levels of female schooling on home productivity.

## **4.4 Discussion of Results**

### *4.4.1 Possible mechanism for the role of education in the decline of the female LFPR*

One potential mechanism that can explain the negative impact of rising women's education on their labor market participation is higher returns to women's home productivity. This could either be a result of an increase in productivity of time spent by women in home production or a change in preferences of women towards home production as they get more education. In either case, if the returns to women's time spent in home production rise faster than the returns to female education in the labor market, then women are likely to withdraw

---

<sup>21</sup> Eswaran et al. (2012) suggest that the decline in women's work force participation and increase in their engagement in 'status' related activities is well predicted by rising household incomes in rural India since 'status' is a normal good.

from the labor market at higher rates as they become more educated. To investigate this potential explanation further we use the same decomposition techniques to analyze one measure of home production - domestic work by women in the household – in the NSS.

As shown in Figure 4, the over two decades' long decline in married women's employment in rural India has occurred alongside increases in the share of women reporting domestic work as their primary activity. Table 6 shows the Blinder-Oaxaca decomposition results for the change in domestic work by women between 1987-1999 and 1999-2011. Women's attributes fully account for the rise in domestic work between 1987 and 1999 (columns (1) and (2)) and account for up to 55 percent of the increase between 1999 and 2011 (columns (3) and (4)) as shown by the row 'explained proportion'.

The rise in women's education over the first decade in our sample accounts for 45 percent of the explained proportion of this change in domestic work at the 1987 regression coefficients (specification 1 of Table 6). Similarly, women's education contributes 29 percent to the explained proportion of the surge in domestic work using the 1999 regression coefficients (specification 3 of Table 6) for the later decade.<sup>22</sup> Controlling for men's education in specifications (2) and (4) reduces these explained proportions by about a third.<sup>23</sup> The growth in household's consumption expenditure also explains a substantial part of the rising proportion of women engaging primarily in domestic work.

To get a better sense of how women might be using their time in domestic work, we analyze patterns in the Indian Time Use Survey from 1998. Unfortunately, because this is the only time use survey data that exist, we cannot assess any changes in domestic activities by

---

<sup>22</sup> The results at 1999 (for change during 1987-1999) and 2011 (for change during 1999-2011) coefficients and using the DFL decomposition of domestic work give us qualitatively similar results, hence have been omitted for brevity.

<sup>23</sup> The rise in women's and men's education explains 17 percent and 75 percent of the increase in domestic work using 1987 regressions coefficients respectively (specification 2 of Table 6) during 1987-1999. Similarly, women's and men's education explains 5 percent and 18 percent of the increase in domestic work using 1999 regressions coefficients (specification 4 of Table 6) during 1999-2011.

married women over the period of our study. Nonetheless, the data provide important details on how much time women spend on domestic chores, including child-care, and how this time varies with women's level of education in the cross section.

We restrict the sample to rural married women ages 25 to 65, who have at least one child in the 0 to 15 year old age group.<sup>24</sup> In Figure 6(a) we show the number of hours that women spend each week on physical care of their children (eg: washing, dressing, feeding, teaching and instruction of own children). The graph suggests that the time spent on child-care increases with the level of education of the woman, particularly when education increases above primary level. In Figure 6(b) we broaden the definition of domestic activities to include time spent on both exclusive child care and other household chores which typically affect child well-being, such as cooking. The data again indicate that more educated women spend a higher proportion of their time on household chores. This appears to decline only at a very high level of education, graduate and above. These patterns lend support, albeit not causal, to our contention that as the average educational attainment of rural women rises from the observed low levels of schooling they engage in more hours of domestic activities, including child care, relative to participating in the labor market. The same key variables that accounted for a substantial part of the predicted decline in female LFPR over time in both decades – that is, the education variables – may also account for a substantial share of the predicted increase in female domestic work, including child care, over the same period. These findings are therefore consistent with increasing relative returns to education in home production being a possible mechanism for the decline in female LFPR in rural India.

---

<sup>24</sup>Time use data were collected from 18,591 households across six states of India by the same nodal agency that conducts the NSS to assess the economic contribution of women. The selection of states was purposive. One state from each region of India was chosen (north-Haryana, centre - Madhya Pradesh, west- Gujarat, east-Orissa, south-Tamil Nadu and north east-Meghalaya), to capture the diversity in gender norms and culture (<http://mdgs.un.org/unsd/Demographic/sconcerns/tuse/Country/India/sourceind99b.pdf>). While the NSS collects data on aggregate domestic work, the time use survey allows us to break down domestic work into various components, other than leisure.

Whether this is due to an increase in their home productivity or a shift in preferences is not something we can test in our data. However, findings from other research support the interpretation that education makes women more productive in the home. First, returns to education in home production may have increased during the period of our study if the returns to children's human capital rose during this period as well. Behrman et al. (1999), using data from the green revolution period in India (1968-1982) find that because households with an educated male member earned larger farm profits, the returns to investing in male education increased. This in turn increased the demand for educated women in the marriage market. Women with primary education spent more time at home and the presence of an educated mother increased time spent by children studying, relative to less educated mothers.

Since rural Indian women have had low initial level of education, recent changes in female education are more likely to have increased women's marginal productivity in the home than in the market, at least for those women with young children - when investments in health and education are critical.<sup>25</sup> Indeed, we find that the decline in the LFPR of women aged 25-45 was greater than the decline for 46-65 year olds in both decades.<sup>26</sup> These younger women are the ones most likely to have young children – almost twice as many 0-14 year old children in the household as women aged 46-65 - in the NSS, and therefore most likely to experience high returns to child-care in the home. A case in point is educational investments. Azam (2012) finds that in urban India, increases in the labor market returns to education during 1993-2004 were much higher for workers with secondary and tertiary education. Similarly, Mendiratta and Gupt (2013) find that there has been an increase in returns to

---

<sup>25</sup> The relative starting position of rural and urban women on the 'U'-curve may therefore account for the different relationships between education and changes in female LFPR between urban (Klasen and Pieters 2015) and rural areas (this paper).

<sup>26</sup> The LFPR of 25-45 year old, married rural women declined 3.4 and 11.2 percentage points during 1987-1999 and 1999-2011, respectively. The corresponding numbers for 46-65 year old women was 1.8 and 7.5.

education in India during 2004-11 but only at more than secondary levels of education. The empirical evidence on changes in returns to schooling in India, thus, is consistent with households investing in more education for their children.

#### *4.4.2 Other factors accounting for the unexplained changes in female LFPR*

While the changes in demographic and socio-economic attributes of women completely explain the fall in their LFPR during 1987-1999, 44 percent or more of the fall in women's LFPR in 1999-2011 remains unexplained. What factors might account for this larger unexplained component in the later period?

The unexplained proportion could reflect changes in the demand for women's labor, also proposed as an explanation for the stagnant women's LFPR in urban India (Klasen and Pieters 2015). A lower demand for female labor will reduce the probability of women's participation in the labor market even when their individual and socio-economic characteristics are unchanged. Structural transformation in the economy, in which labor reallocates out of agriculture and into other sectors, as has occurred in India during the last couple of decades, could impact female employment through this labor demand channel (Goldin 1995). Typically, wages in the agriculture sector are the lowest in India and hence females are likely to withdraw from this sector as education and real income growth raise their reservation wages.<sup>27</sup> Other sectors – construction, manufacturing and services - should then grow at a pace that can absorb labor that has withdrawn from agriculture. While economic growth in India in the last few decades has resulted in a decline in the contribution of agriculture to employment growth, it has failed to create concomitant growth in the manufacturing sector where most women with middle to secondary levels of education and

---

<sup>27</sup> Authors' calculations show that in 2011 the daily wage in agriculture, manufacturing, construction and services sectors were Rs. 100, Rs. 119, Rs. 116 and Rs.209, respectively.

from middle income groups are likely to look for employment (Chandrasekhar and Ghosh 2011). During 1999 and 2011, female employment in agriculture fell by 13 percentage points, and was stable in manufacturing at around 3.7 percent. Female employment in the construction sector rose by only 4 percentage points while there was a small increase in the services sector from 2.8 percent in 1999 to 3.3 percent in 2011 (authors' calculations from the NSS 1999 and 2011). Thus, economic growth has not been able to absorb female workers leaving agricultural work (Chowdhury 2011; Kannan and Raveendran 2012). A rise in women's own education coupled with lack of jobs commensurate with higher reservation wages may contribute to the continued decline in female LFPR, especially in the second decade of our sample.<sup>28</sup>

## 5. Conclusion

In India, women's labor force participation rates have fallen dramatically since the late 1980s. This period was also characterized by rapid income growth and improvements in educational attainment. We show that the decline in LFP has been concentrated among rural, married women. This group has also increased their participation in domestic work over the same period.

We use parametric and semi-parametric decomposition techniques to estimate the proportion of the fall in women's LFPR that is accounted for by the changing observable characteristics of working age women. These observable attributes can account for a large, albeit falling, share of the decline in women's LFPR. While the fall in women's LFPR between 1987 and 1999 is completely explained by the changes in women's demographic and

---

<sup>28</sup> The observation that the distribution of caste and religious groups – important predictors of social norms regarding women's work force participation in India (Eswaran et al. 2012) - has not changed significantly during 1987-2011 suggests that it is unlikely that social norms either changed significantly or were a significant unexplained determinant of the decline in women's LFPR during the period of our study.

socio-economic characteristics, these factors account for at most 56 percent of the decline between 1999 and 2011. This leaves a substantial role for unobservables to account for the decline in female LFPR, in the post-1991 reform period.

The decomposition exercise shows that increases in women's own education and that of the men in their household play the most important role in explaining the decline in female LFPR in both decades. At a minimum, increases in women's and men's education explain at least 22 percent and 53 percent of the total decline between 1987 and 1999 respectively. Similarly, increases in education of women and men account for at least 8 percent and 16 percent of the decline in rural women's LFPR between 1999 and 2011, respectively. The fact that increasing education plays such a strong role in accounting for the *decline* of women's work is puzzling at face value. However, we highlight that the observed fall in women's LFPR in India in the previous three decades is coupled with an increasing proportion of women engaging primarily in domestic, non-remunerative activities.

We suggest a hitherto ignored explanation for the fall in women's LFPR - the role of women, and more educated women in particular, in home production. Women's decisions about working in the market or at home depend on the relative returns to time spent in each sector. If women get more education but the returns to women's home production rise more than the returns in the labor market for educated females, women are likely to withdraw from the labor force and engage in domestic work. We provide evidence that suggests that this may be one credible and important factor, among others proposed in the existing literature, in explaining the long-term trend of declining women's LFPR in rural India.

Rural sample

Source: NSS (1987, 1999, 2011) Employment and Unemployment Schedule (Authors' calculations).

Note: The sample includes women aged 25-65 in rural India. The above graph reports proportion of women whose primary activity is domestic work.

**Figure 5. Female Labor Force Participation Rates (LFPR) over time by education level**  
Rural sample of married women

Source: NSS (1987, 1999, 2011) Employment and Unemployment Schedule (Authors' calculations).

Note: The sample includes women aged 25-65 in rural India. 'High Sec' refers to secondary and higher secondary level of education. Bars show means of LFPR by level of education for each NSS survey year by education category. The lines connect the means across education categories.

**Figure 6. Female time spent in childcare activities by education level**  
Sample of rural, married women aged 25-65 living with at least one child aged 0 to 15

*Source:* Author's calculations from the 1998 Indian Time Use Survey.

*Note:* Graph (a) plots hours spent in a week on exclusive child-care. This includes time spent on the following activities by a woman: Physical care of children (washing, dressing, feeding), teaching training and instruction of own children, accompanying children to doctor/school/sports/other, supervising children, travel related to care of children. Graph (b) plots hours spent in a week on exclusive child-care and other domestic chores which indirectly add to children's well-being or can be done while supervising children. This includes time spent on cooking and cleaning house, clothes and utensils along with the activities in exclusive child-care. 'High Sec' refers to secondary and higher secondary level of education. The total number of observations is 7,593.

Note: Table shows coefficients (marginal effects) from the logit regressions of female LFP on covariates.

Regressions include sampling weights provided in the NSS. The cut-offs for consumption expenditure deciles for the year 1987 are used and adjusted for cost of living for 1999 and 2011. The sample includes 25-65 year old, rural married women. Standard errors in parenthesis. \*\*\*, \*\*, \* significant at 1%, 5% and 10%, respectively.

Male education in HH				Yes	Yes

*Note:* A woman is defined to be in labor force if she is working or seeking work as her primary or subsidiary activity. LFPR is the share of women in the labor force. The sample includes rural married women aged 25-65. The analysis incorporates the sampling weights in NSS. Explained proportion is calculated by dividing the explained component by the change in predicted LFPR (e.g. in the first column:  $0.0210/0.0310 = 0.68$ ). The change in predicted LFPR varies marginally across columns in Panel A and B because the number of observations varies due to missing data for certain variables. Because our decomposition subtracts 1999 from 1987 (or 2011 from 1999), and female LFPR are falling over time, the changes in LFPR are positive.

*Note:* A woman is defined to be in the labor force if she is working or seeking work as her primary or subsidiary activity. LFPR is the share of women in the labor force. The sample includes rural married women aged 25-65. The analysis incorporates the sampling weights in NSS. The specification in column (6) includes two-way interactions between all the variables when estimating the re-weighting function. See the Methodology section for an explanation of the semi-parametric DFL (Dinardo-Fortin-Lemieux) decomposition technique.

*Note:* The dependent variable is a dichotomous variable: a woman is engaged in domestic work if her primary status during the last year was domestic work. The sample includes rural married women aged 25-65. The analysis incorporates the sampling weights in NSS. The explained proportion is the explained component divided by the change in predicted domestic work. Figures in bold are the shares of the overall predicted variation accounted for by a specific characteristic and are estimated by dividing the component explained by the characteristic (below the bold figures) by the explained component for that specification. Standard errors in parenthesis. \*\*\*, \*\*, \* significant at 1%, 5% and 10%, respectively.

## **Appendices**

### **Appendix A: Definition of Labor Force Participation Rate**

The National Sample Survey uses three reference periods for the employment survey (i) one year, (ii) one week and (iii) each day of the previous week. This paper employs the Usual Principal and Subsidiary Status (UPSS) definition. The activity status on which a person spent relatively longer time (major time criterion) during the 365 days preceding the date of survey is considered the Usual Principal Activity Status of the person. Persons are first categorized as those in the labor force and those out of the labor force depending on the major time spent during the 365 days preceding the date of survey. For persons belonging to the labor force, the broad activity status of either 'working' (employed) or 'not working but seeking and/or available for work' (unemployed) is then determined based on the time criterion. After determining the principal status, the economic activity on which a person spent 30 days or more during the reference period of 365 days preceding the date of survey is recorded as the Subsidiary Economic Activity Status of a person. In case of multiple subsidiary economic activities, the major activity and status based on the relatively longer time spent criterion is considered. If a person is defined to be in the labor force in either the principal activity status or the subsidiary activity status then she is defined to be in the labor force according to the UPSS. A woman who reports her primary activity is domestic production is classified as out of the labor force.

## Appendix B: Explaining the role of interactions in the decomposition

The three-way linear Blinder-Oaxaca decomposition for change in mean outcome of employment(Y) between 1999 and 2011 can be written as:

$$\begin{aligned} & \bar{Y}^{1999} - \bar{Y}^{2011} \\ &= X^{1999}\beta^{1999} - X^{2011}\beta^{2011} \\ &= (X^{1999} - X^{2011})\beta^{2011} + X^{2011}(\beta^{1999} - \beta^{2011}) + (X^{1999} - X^{2011})(\beta^{1999} - \beta^{2011}) \end{aligned}$$

Here, the first term is the *ceteris paribus* effect of a change in characteristics, the second term is the *ceteris paribus* effect of a change in coefficients and the third term is the interaction effect between the changing characteristics and the changing coefficients (Biewen 2012). The corresponding non-linear decomposition for the change in mean employment (Y) is

$$\begin{aligned} & \bar{Y}^{1999} - \bar{Y}^{2011} \\ &= \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{1999})}{N^{1999}} - \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{2011})}{N^{2011}} \\ &= \left( \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{2011})}{N^{1999}} - \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{2011})}{N^{2011}} \right) \\ &+ \left( \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{1999})}{N^{2011}} - \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{2011})}{N^{2011}} \right) \\ &+ \left[ \left( \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{1999})}{N^{1999}} - \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{1999})}{N^{2011}} \right) \right. \\ &\quad \left. - \left( \sum_{i=1}^{N^{1999}} \frac{F(\mathbf{X}_i^{1999} \hat{\beta}^{2011})}{N^{1999}} - \sum_{i=1}^{N^{2011}} \frac{F(\mathbf{X}_i^{2011} \hat{\beta}^{2011})}{N^{2011}} \right) \right] \end{aligned}$$

The last term in the square brackets is the interaction effect, which is equal to the explained component at 2011 coefficients subtracted from the explained component at the 1999 coefficients. We show an example of including the interaction term in the decomposition in Table B.1 below.

**Table B.1: Blinder-Oaxaca Decomposition of Change in Women's LFPR (Three-way)**

Observations	129,941		118,405	

*Note:* The first row against each characteristic in the above table reflects the proportion of contribution of a characteristic to the explained component of the decomposition. It is estimated by dividing the component explained by the characteristic (below the bold figures) by the explained component for that specification. Rounding off errors. Standard errors in parenthesis. \*\*\*, \*\*, \* significant levels at 1%, 5% and 10%, respectively.

The International Growth Centre  
(IGC) aims to promote sustainable  
growth in developing countries  
by providing demand-led policy  
advice based on frontier research.
